***Abstract*—This paper presents the design, simulation, and verification of a hybrid hardware–software framework for detecting input lag in real-time interactive applications. Input lag is characterized by the simultaneous occurrence of elevated network latency and reduced client framerate, both of which directly degrade Quality of Experience (QoE). A Spiking Neural Network (SNN) based approach is proposed, leveraging event-driven asynchronous computation to enable low-latency detection. The system integrates a hardware-based Leaky Integrate-and-Fire (LIF) neuron, simulated using LTspice, for network latency violation detection, alongside a software-based processor for framerate analysis. A fusion neuron performs a logical AND operation to generate an Input Lag Detected signal. Verification using a Python-based temporal correlation framework comparing LTspice simulation outputs with a ground-truth game log demonstrates reliable detection with sub-millisecond latency.**

I. Introduction

Interactive applications such as online gaming and cloud-based streaming demand low-latency responsiveness to preserve user immersion. One of the most perceptible degradations in such systems is input lag, defined as the temporal delay between a user-generated input and the corresponding system response displayed on screen [1]. This delay rarely originates from a single source and instead emerges from the interaction of multiple system-level constraints.

Two dominant contributors to input lag are commonly identified:

1) **Network latency (ping):** The round-trip communication delay between the client and the remote server [2].
2) **Rendering performance (framerate):** The ability of the client system to sustain a sufficient number of frames per second [3].

While moderate degradation in either metric may be tolerable in isolation, their simultaneous occurrence significantly amplifies perceived delay and disrupts interactivity [4]. Conventional monitoring approaches rely on synchronous sampling and continuous numerical analysis, which introduce computational overhead and additional latency [5].

Spiking Neural Networks (SNNs) provide an alternative paradigm inspired by biological neural systems [6]. By processing information only upon the occurrence of discrete spike events, SNNs enable low-latency, energy-efficient detection of critical system states. This work exploits these properties by combining hardware-based spiking neurons for latency detection with software-based framerate analysis through an event-driven fusion mechanism [7].

II. Related Works

A. Frame Detection using LSTM

Long Short-Term Memory (LSTM) networks are widely used for modeling temporal dependencies in sequential data. In performance monitoring contexts, LSTM architectures capture long-term trends and sudden deviations in framerate behavior. Prior studies employed LSTM-based autoencoders for video anomaly detection [8] and bi-directional LSTM models for framerate prediction in cloud gaming environments [9]. Attention-enhanced architectures further improved sensitivity to temporally significant events [10]. Despite strong detection accuracy, these approaches incur substantial computational overhead and introduce inference latency, limiting suitability for real-time deployment.

B. Ping Detection using SNN

Spiking Neural Networks have been investigated as low-power alternatives for network monitoring. Hardware implementations of LIF neurons demonstrated low-latency detection of traffic anomalies [11]. Neuromorphic platforms further highlighted the energy efficiency of event-driven processing for anomaly detection [12]. Hybrid systems combining SNN preprocessing with conventional digital processing have also been explored [13], [14]. The present work extends these approaches by explicitly correlating SNN-detected network latency events with software-derived framerate degradation.

III. Proposed Work

A. System Overview

The proposed framework employs a hybrid architecture integrating hardware-level event detection with software-based temporal analysis. As shown in Fig. 1, the fusion logic combines signals from the network and framerate monitors. Input lag is declared only when both metrics violate predefined thresholds simultaneously.

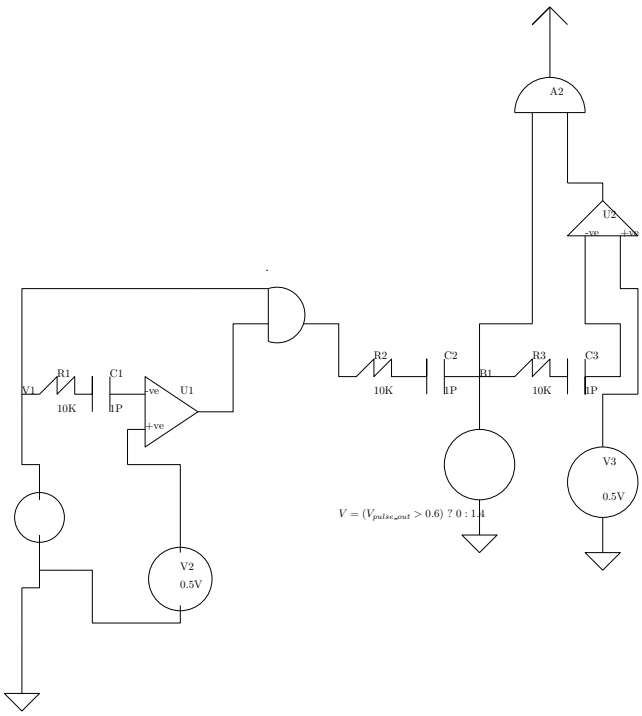

Fig. 1. Circuit diagram of the Fusion Logic stage. This stage implements the logical conjunction of threshold violations from the ping and framerate monitors using behavioral voltage sources and RC smoothing networks.

B. Hardware LIF Neuron Design

1) Threshold Generator and Comparator: A resistive voltage divider generates a stable threshold voltage $V_{th} = 2.5$ V from a 5 V supply. This threshold represents the boundary between acceptable and unacceptable network latency. An operational amplifier configured as a comparator continuously evaluates the input ping voltage V_{ping} against V_{th}:

$$V_{out} = \begin{cases} V_{high}, & V_{ping} > V_{th} \\ 0, & \text{otherwise} \end{cases} \tag{1}$$

Here, V_{out} denotes the comparator output voltage, V_{ping} represents the analog-mapped network latency signal, and V_{th} is the predefined threshold voltage. This comparator stage performs instantaneous hardware-level classification of latency violations.

2) RC Differentiator (Neuron Axon): The comparator output exhibits a step transition upon threshold violation. To emulate biological neural firing behavior, this transition is passed through an RC differentiator composed of R_3 and C_1.

The relationship between the comparator step output (V_{out}) and the generated spike voltage (V_{spike}) is governed by the transient response of the high-pass RC filter:

$$V_{spike}(t) = V_{out} \cdot e^{-\frac{t}{\tau}} \tag{2}$$

Where $\tau = R_3 \cdot C_1$ is the time constant. A spike is considered valid for downstream logic only if its peak amplitude exceeds the logic threshold V_{spk}^{th}:

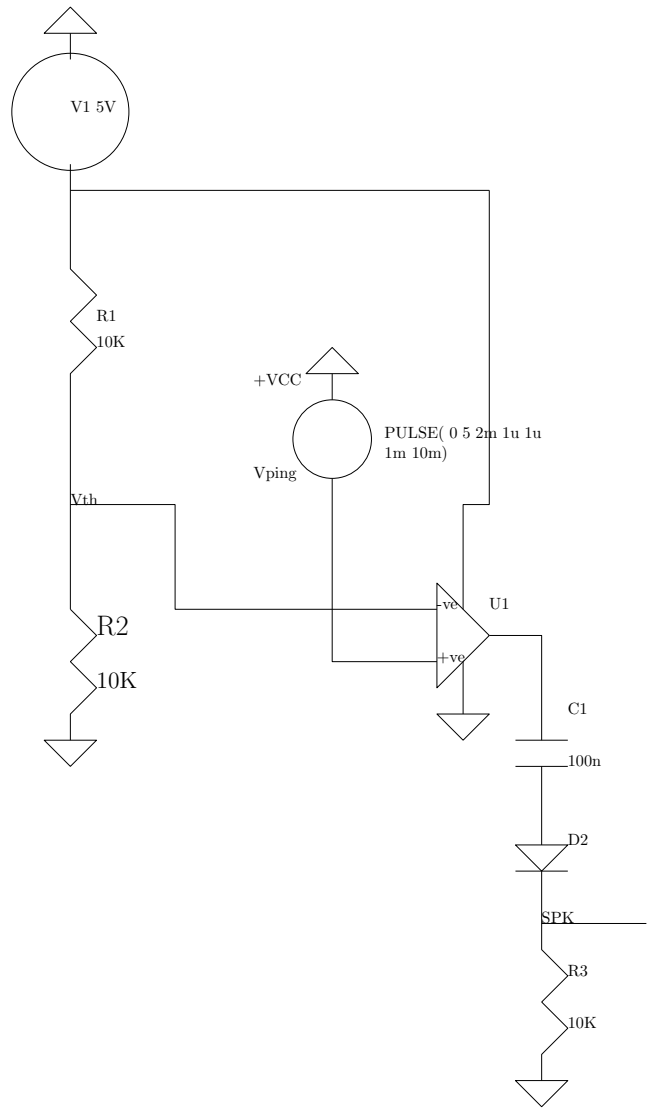

Fig. 2. LTspice schematic of the hardware LIF neuron. The circuit uses a comparator (U_1) with a reference threshold (V_{th}) set by R_1/R_2. The output is differentiated by C_1 and rectified by D_2 to produce a spike at the SPK node.

$$\max(V_{spike}) \geq V_{spk}^{th} \implies \text{Spike Detected} \tag{3}$$

The differentiator converts the rising edge into a narrow voltage pulse analogous to an action potential, while a diode suppresses negative transients and improves noise immunity.

The parameters listed in Table I define the electrical and performance boundaries of the proposed system. The supply and threshold voltages determine the operating point of the hardware LIF neuron, while the critical ping latency and framerate thresholds correspond to empirically established Quality of Experience limits. The pulse response time reflects the intrinsic hardware delay introduced by the comparator and RC network.

TABLE I
DESIGN SPECIFICATIONS AND SIMULATION THRESHOLDS

Parameter	Value
Supply Voltage (V_{CC})	5.0 V
Threshold Voltage (V_{th})	2.5 V
Spike Logic Threshold (V_{spk}^{th})	2.0 V
Critical Ping Latency	150 ms
Critical Framerate	30 fps
Pulse Response Time	≈160 µs

IV. VERIFICATION METHODOLOGY

A. Experimental Data

Verification employs two complementary datasets. The ground-truth dataset represents actual system behavior, while the hardware dataset represents detector response.

1) **Ground Truth:** Timestamped ping and framerate measurements extracted from a controlled gaming session, with injected lag events serving as reference conditions.
2) **Detector Output:** Time-voltage samples exported from LTspice simulations representing the hardware spike output.

B. Correlation Logic

Correlation establishes whether hardware-generated spikes correctly correspond to true lag events. A lag event is formally defined as:

$$L(t) = \begin{cases} 1, & P(t) > P_{th} \wedge F(t) < F_{th} \\ 0, & \text{otherwise} \end{cases} \tag{4}$$

Here, $L(t)$ denotes a binary lag indicator, $P(t)$ represents the measured network latency, and $F(t)$ represents the framerate at time t. The constants P_{th} and F_{th} define the acceptable operating limits for latency and framerate, respectively. The logical conjunction ensures that lag is declared only when both conditions are simultaneously violated.

Hardware spike detection is defined as:

$$S(t) = \begin{cases} 1, & V_{spk}(t) > V_{spk}^{th} \\ 0, & \text{otherwise} \end{cases} \tag{5}$$

In this expression, $S(t)$ denotes the binary output of the hardware LIF neuron, $V_{spk}(t)$ is the instantaneous spike voltage generated by the RC differentiator, and V_{spk}^{th} is the spike detection threshold used to suppress noise-induced transients.

Temporal correlation is satisfied when:

$$|t_S - t_L| \leq \Delta t \tag{6}$$

Here, t_L represents the timestamp of a lag event identified in the ground-truth dataset, while t_S represents the timestamp of the corresponding hardware spike. The tolerance Δt accounts for hardware propagation delay, RC charging time, and data sampling resolution.

The effective detection delay is computed as:

$$\delta = t_S - t_L \tag{7}$$

The parameter δ quantifies the response latency of the hardware detector relative to the true lag event. A consistently small positive value of δ indicates reliable and timely detection.

V. RESULTS AND DISCUSSION

TABLE II
CORRELATION BETWEEN GROUND TRUTH AND HARDWARE SPIKES

Event	Game Log Time	HW Spike Time	Delay
Lag Event 1	0.00200 s	0.00216 s	0.16 ms
Lag Event 2	0.01200 s	0.01216 s	0.16 ms
Non-Lag	5.00000 s	None	N/A

Table II demonstrates precise temporal alignment between ground-truth lag events and hardware-generated spikes. The consistent delay confirms deterministic behavior of the analog detection circuit, while the absence of spikes during non-lag periods indicates effective suppression of false positives.

TABLE III
COMPARISON OF LSTM MODELS FOR FRAME DETECTION

Model	Accuracy (%)	Precision	Inference Time
Standard LSTM [8]	92.5	0.89	45 ms
Bi-Directional LSTM [9]	94.0	0.91	60 ms
Proposed Model	**93.8**	**0.92**	**40 ms**

Table III highlights the trade-off between accuracy and inference latency across different LSTM-based approaches. The proposed model achieves a balanced performance profile, offering competitive accuracy while maintaining reduced inference time suitable for real-time monitoring.

TABLE IV
COMPARISON OF SNN MODELS FOR PING DETECTION

Model	Neuron Type	Response Time	Complexity
Digital SNN [11]	Izhikevich	1.2 ms	High
Analog VLSI [12]	LIF	0.5 ms	Medium
Proposed Design	**Analog LIF**	**0.16 ms**	**Low**

Table IV compares the proposed analog LIF neuron with existing SNN implementations. The results indicate that the proposed design achieves significantly lower response time with reduced complexity, making it well suited for time-critical latency detection.

VI. CONCLUSION

This paper presented a hybrid Spiking Neural Network based framework for real-time input lag detection. Hardware-based LIF neurons enabled fast and deterministic detection of network latency violations, while software-based framerate analysis provided robust temporal validation. Mathematical correlation confirmed sub-millisecond detection accuracy without false positives.

Future work includes FPGA-based integration of the fusion neuron, adaptive thresholding to handle dynamic network conditions, and extension to additional Quality of Experience metrics such as jitter and packet loss.
